XRF analysis by the fusion method for oxide powder on a benchtop WDXRF spectrometer Supermini

Yasujiro Yamada*

1. Introduction

The fusion method in X-ray fluorescence (XRF) analysis is an effective sample preparation technique for getting accurate analysis results of powder samples, since the technique eliminates heterogeneity due to grain size and mineralogical effect. In addition, the homogenization of material property by vitrification makes it possible to expand the calibration range, such as making synthetic calibration curves by the use of reagents or applying the calibration to diverse materials.

A benchtop wavelength-dispersive X-ray fluorescence (WDXRF) spectrometer Supermini is compact and yet has excellent resolution and sensitivity for light elements. This report demonstrates that single calibration for diverse minerals and ores was established by the fusion method on the Supermini.

2. Problems and solutions of the fusion method applied to diverse materials

XRF is an analysis method using calibration curves prepared with standard samples for each kind of material to be analyzed. For the analysis of various minerals and ores, however, the number of standard samples available in the market for every kind of material is limited.

Meanwhile, the best fusion condition for making fusion beads is different for each kind of material. For example, a typical dilution ratio of sample to flux in weight is 10:1, but in the case of samples containing high transition metals, it should be a higher dilution ratio 20:1 to make proper fusion beads. In addition, chromemagnesia refractory samples require additional oxidizing agent during the fusion.

Crystallization water, carbonate and so on may cause loss on ignition (LOI) due to evaporation of H₂O or CO₂ during the fusion. On the other hand, there is a case of gain on ignition (GOI), such as iron ore, due to oxidization of the component.

In the case of analysis for diverse materials, there is another problem where the difference in major elements among variety of sample materials causes the difference of absorption and enhancement effect to fluorescent X-rays emitted from the samples. This effect results in analysis error.

The problems stated above are summarized as following three factors causing analysis error,

(1) Difference in dilution ratio of flux and oxidizing

agent to sample (2) LOI and GOI (3) Matrix effect.

For (1), it is possible to apply correction for dilution ratio of the flux to the sample and, if necessary, additional correction for weight ratio of oxidizing agent component left in the bead to the sample. About oxidizing agent (e.g. LiNO₃), a part of the agent (e.g. NO_2) is evaporated during the fusion and the rest (e.g. Li₂O) is left in the bead. The correction coefficients can be calculated by the use of the fundamental parameter method (hereafter FP method).

For (2), it is possible to compensate for the influence of LOI and GOI by treating LOI and GOI as nonmeasured component (balance component) in the matrix correction formula.

For (3), it is necessary to apply the proper matrix correction model as in the conventional way, where the correction coefficients can be obtained by the FP method.

The solutions for the problems (1), (2) and (3) have been already reported⁽¹⁾⁻⁽³⁾. The correction formula will be described below.

The dilution ratios of the flux to the sample R_F and the weight ratio of the oxidizing agent component left in the bead to the sample (hereafter oxidizer ratio) R_{χ} are expressed as follows,

$$R_F = \overline{R}_F + \Delta R_F \tag{1}$$

$$R_X = R_X + \Delta R_X \tag{2}$$

where R_F is the standard dilution ratio, \overline{R}_X the standard oxidizer ratio, ΔR_F the difference between the dilution ratio and the standard dilution ratio, and ΔR_X the difference between the oxidizer ratio and the standard dilution ratio.

The calibration equation with correction terms of dilution ratio and oxidizer ratio is expressed as follows,

$$C_{i} = (A_{i}I_{i} + B_{i}) \left(1 + \sum_{j} \alpha_{j}C_{j} + \alpha_{F}\Delta R_{F} + \alpha_{X}\Delta R_{X} \right)$$
(3)

: weight fraction of the analyte in the sample

- C_i C_i : weight fraction of the coexisting component in the sample
- A_i, B_i : calibration constants
- : matrix correction coefficient for component *j* α_i
- : matrix correction coefficient for the flux α_{F}

^{*} SBU WDX, X-ray Analysis Division, Rigaku Corporation.

α_X : matrix correction coefficient for the oxidizing agent component left in the bead.

Substituting the equations (1) and (2) into the equation (3), the following equation is obtained,

$$C_{i} = (A_{i}I_{i} + B_{i}) \left(1 + \sum_{j} \alpha_{j}C_{j} + K_{i} + \alpha_{F}R_{F} + \alpha_{X}R_{X} \right)$$
(4)
where $K_{i} = -(\alpha_{F}\overline{R}_{F} + \alpha_{X}\overline{R}_{X}).$

Since K_i is a constant, it is possible to use the actual weights for the flux, sample and oxdizing agent for the dilution ratio and the oxidizer ratio, which results in accurate corrections for the described losses and gains.

The correction coefficient α_j , α_F and α_X are calculated by the use of the FP method, where the effect of LOI and GOI is compensated by applying the correction model in which the balance component is designated as the base component.

3. Expansion of analysis range by the use of reagents in the fusion method

Standard samples commercially available are quite limited as mentioned above. One of the features of the fusion method is that the standard samples for calibration can be made with synthetic oxides.

When making synthetic standard beads by the use of reagents, typically two or more reagents are mixed to make a fusion bead. In the analysis of this report, however, to simplify the procedure, a single reagent was used to make a fusion bead for expanding the quantitation range for each analyte. The analytes, the reagents used and the procedure for expanding the calibration range are shown below.

$[Na_2O]$

Sodium carbonate (Na₂CO₃) was dried at 230°C, weighed out so that the residual Na₂O become 25 mass% in the fusion bead with the dilution ratio 10:1 and then fused. The balance was 75%, treated as LOI.

$[Al_2O_3]$

Alumina (Al_2O_3) was baked at 1050°C, weighed out so that Al_2O_3 become 100 mass% in the fusion bead with the dilution ratio 10:1 and then fused.

$[P_2O_5]$

Lithium Phosphate (Li_3PO_4) was dried at 700°C, weighed out so that the residual P_2O_5 become 25 mass% in the fusion bead with the dilution ratio 10:1 and then fused.

$[K_2O]$

Potassium Carbonate (K_2CO_3) was dried at 230°C, weighed out so that the residual K_2O become 50 mass% in the fusion bead with the dilution ratio 10:1 and then fused.

[CaO]

Calcium Carbonate (CaCO₃) was dried at 230° C, weighed out so that the residual CaO become 100 mass% in the fusion bead with the dilution ration 10:1 and then fused. The expanded calibration covers quick lime.

$[TiO_2]$

Titanium Oxide (TiO₂) was dried at 1000°C, weighed out so that the TiO₂ become 10 mass% in the fusion bead with the dilution ratio 10:1 and then fused.

4. Standard materials and calibration range

Table 1 shows the standard reference materials used in this analysis. Thirty nine standard materials of talc, high purity silica, feldspar, dolomite, bauxite, iron ore, cement, phosphate rock and others were used. Table 2 shows the concentration range of the standard materials used and also the calibration range including synthetic oxide standard samples mentioned above. The range for MgO, Al₂O₃, SiO₂, Fe₂O₃, ZrO₂, etc. is from a trace to 90 mass% or higher and the range for P₂O₅ CaO, Cr₂O₃ is 30–60 mass%. In addition, the calibration is applicable to samples with up to 50 mass% LOI.

5. Sample preparation

In the fusion, lithium tetra borate ($\text{Li}_2\text{B}_4\text{O}_7$), pre-dried at 675°C, was used as flux and lithium nitrate (LiNO_3) as oxidizing agent. The dilution ratio of the flux to the sample in weight was 20:1 only for magnesite chrome and chrome-magnesia refractory and 10:1 for the others.

The oxidizing agent LiNO_3 was used only for chrome-magnesia refractory and the weight ratio of LiNO_3 to the sample was 10:1. LiNO_3 is evaporated during the fusion by the following reaction,

 $2LiNO_3 \rightarrow Li_2O + 5/2O_2 \uparrow + N_2 \uparrow$

and, therefore, the residual component of the oxidizing agent left in the fusion bead is Li_2O . Accordingly, the weight ratio of the residual component to the sample

("oxidizer ratio" mentioned earlier in Clause 2) is 2.1668.

The samples were fused on Rigaku benchtop highfrequency fusion machine, Bead Sampler. The fusion temperature was 1200°C for all materials except for Portland cement, which was fused at 1075°C to prevent volatilization of sulfur, one of the analytes.

6. Instrument and measurement condition

Each fusion bead was measured in vacuum on the Supermini, a benchtop WDXRF spectrometer, which was equipped with an end-window Pd-target 200W X-ray tube, operating at 50 kV-4.0 mA, with the measurement area 30 mm in diameter. Details of the measurement conditions are shown in Table 3. The measurement time for the analysis of the 15 components per sample was about 12 minutes.

7. Calibration and analysis results

The calibration results are summarized in Table 4 and the calibration curves are shown in Figs. 1–15.

With respect to matrix correction, since samples containing a large amount of LOI were fused to make fusion beads, the de Jongh model in which all analytes were correcting components was applied to calculate theoretical matrix correction coefficients. LOI (and GOI) was designated as the balance and the base component to compensate for the influence of LOI (and GOI)

Component	Calibration Range (mass%)	Accuracy (mass%)	Fig.
SiO ₂	0.2 – 99.78	0.27	1

Table 4. Calibration range and accuracy.

though LOI (or GOI) content is unknown.

Even though various standard materials and additional synthetic standards were used for making the calibration curves, excellent accuracy was obtained for each and all of the analytes.

When an element line of an analyte is interfered with by other element lines, it is necessary to apply appropriate overlap correction. In this analysis, correction for overlap of Zr-L α to P-K α , of Cr-K β 1 to Mn-K α , of P-K α to Zr-L α and Zr-L γ 1 on S-K α was carried out.

For the typical analytes, the details are explained.

 $[SiO_2]$

Figure 1 shows the calibration curve of SiO_2 . Excellent accuracy 0.27 mass% was obtained though the calibration range was expanded from 0 to almost 100 mass% by including high purity silica as a standard sample. The typical materials are shown in the figures.

Although LOI-rich limestone and dolomite, and chrome-magnesia with the different dilution ratio are included, the calibration curve shows a good fit with appropriate correction applied.

Fig. 1. SiO₂ calibration curve.

 $[Al_2O_3]$

Figure 2 shows the calibration curve of Al_2O_3 . In spite of the wide calibration range from 0 to 100 mass% by including Al_2O_3 synthetic bead, excellent accuracy 0.26 mass% was obtained.

The plot of the synthetic Al_2O_3 bead is right on the line by regression with the reference materials. Regardless of variation of LOI content and dilution ratio with wide variation of the standard samples, the calibration curve shows a good fitting.

Fig. 2. Al₂O₃ calibration curve.

[MgO]

Figure 3 shows the calibration curve of MgO. Excellent accuracy 0.18 mass% was obtained for calibration range up to $\sim 97 \text{ mass}\%$ of high purity magnesia. In spite of a lack of standards between 50–90 mass%, the calibration curve shows a good linearity from low concentration to high concetnration, which means that it is possible to quantify MgO content through this calibration range.

Fig. 3. MgO calibration curve.

 $[Na_2O]$

Figure 4 shows the calibration curve of Na_2O . The Na_2O 25 mass% synthetic bead out of sodium carbonate agent (indicated as Na_2O 25) is plotted right on the regression line with the standard materials, which demonstrated that a calibration range can be extended easily by the use of a single component agent to make a synthetic standard bead. In addition, the calibration curve shows an excellent linearity with wide variation of the materials.

Fig. 4. Na₂O calibration line.

[CaO]

Figure 5 shows the calibration curve of CaO, which includes the fusion bead made with $CaCO_3$ agent at the dilution ratio 10:1 as the component CaO is 100 mass% (indicated as CaO 100). In spite of wide variety of the material and LOI content, the calibration curve shows a good linearity up to 100 mass%.

8. Summary

This report demonstrated that the fusion method and the corrections for LOI/GOI and the dilution ratio of flux and oxidizing agent enable a single calibration with the wide range of concentration and for diverse natural minerals and ores. In addition, it was also shown that it is possible to extend the calibration range by the use of a single agent to make a synthetic standard fusion bead.

The Supermini is a benchtop WDXRF spectrometer equipped with an air-cooled 200 W X-ray tube to deliver excellent sensitivity and resolution from light elements to heavy elements while eliminating typical installation requirements, such as cooling water, special power

supply and large floor space. Therefore, this model can be used for analysis of wide variety of natural minerals and ores under various environments.
